Abstract—The current framework of network utility maximization for distributed rate allocation assumes fixed channel code rates. However, by adapting the physical layer channel coding, different rate-reliability tradeoffs can be achieved on each link and for each end user. Consider a network where each user has a utility function that depends on both signal quality and data rate, and each link may provide a ‘fatter’ (‘thinner’) information ‘pipe’ by allowing a higher (lower) decoding error probability. We propose two distributed, pricing-based algorithms to attain optimal rate-reliability tradeoff, with an interpretation that each user provides its willingness to pay for reliability to the network and the network feeds back congestion prices to users. The proposed algorithms converge to a tradeoff point between rate and reliability, which is proved to be globally optimal for codes with sufficiently large codeword lengths and user utilities with sufficiently negative curvatures.

I. INTRODUCTION

Since the publication of the seminal paper [1] by Kelly *et al.* in 1998, the framework of Network Utility Maximization (NUM) has found many applications in network rate allocation algorithms and Internet congestion control protocols, *e.g.*, in [2], [3], [4], [5]. Consider a communication network, wireless or wired, with L logical links, each with a fixed capacity of c_l bps, and S sources (*i.e.*, end users), each transmitting at a source rate of x_s bps. Each source s emits one flow, using a fixed set $L(s)$ of links in its path, and has a utility function $U_s(x_s)$. Each link l is shared by a set $S(l)$ of sources. NUM, in its basic version solved by a standard distributed algorithm, is the following problem of maximizing the total utility of the network $\sum_s U_s(x_s)$, over the source rates $\mathbf{x}$, subject to linear flow constraints $\sum_{s \in S(l)} x_s \leq c_l$ for all links l :

$$\begin{aligned} & \text{maximize}_{\mathbf{x}} && \sum_s U_s(x_s) \\ & \text{subject to} && \sum_{s \in S(l)} x_s \leq c_l, \quad \forall l, \\ & && \mathbf{x} \geq 0. \end{aligned} \quad (1)$$

A major limitation of formulation (1) is that physical layer opportunities are entirely ignored. On links where physical layer’s adaptive resource allocation can change the information ‘pipe’ sizes, *e.g.*, through power control and adaptive coding, each link capacity c_l is no longer a fixed constant but a *function* of resource allocation [6]. For example, changing the code rate on a link changes both the attainable throughput and decoding error probability on the link. A larger c_l can be obtained on a link at the expense of lower decoding reliability,

which in turn lowers the end-to-end signal quality for sources traversing the link and reduces user utilities at those sources if utilities depend on both rate x_s and reliability. Dynamic adjustment of reliability provides an additional degree of freedom for improving each user’s utility as well as the system efficiency. For example, if we allow lower decoding reliability on more congested links and higher decoding reliability on less congested links, we may be able to improve end-to-end joint rate-reliability performance for all users. Such physical layer opportunities are to be leveraged in both wireless systems and wired networks such as DSL broadband access. However, the standard distributed algorithm based on congestion prices (*e.g.*, [1], [4]) cannot be applied since the concept of noisy link and physical layer coding are absent from the basic NUM formulation (1).

In this paper, we exploit the tradeoff between information data rate and signal reliability attained for each source, by controlling the code rate, or equivalently, decoding error probability, for each source’s flow on each link and end-to-end information data rate of each sources’ flow. As in [6], we study a joint transport and physical layer problem in the context of ‘layering as optimization decomposition’. In contrast to [6], where power control is considered at the physical layer, in this paper, we consider reliability of each link through error control coding at the physical layer. The new optimization formulation we propose in general has coupled and nonconvex constraints. Two pricing-based distributed algorithms proposed converge to the globally optimal rate-reliability tradeoff under certain sufficient conditions. Two approaches will be examined: the *integrated dynamic reliability policy*, where a link provides the same error probability (*i.e.*, the same code rate) to each of the sources whose flows traverse it, and the *differentiated dynamic reliability policy*, where a link can provide a different error probability (*i.e.*, a different code rate) to each of the sources.

II. SYSTEM MODEL

We assume that each source s has a utility function $U_s(x_s, R_s)$, where x_s is an information data rate and R_s is reliability of received bits of an elastic traffic source s . Similar to most models based on NUM, we assume that U_s is a smooth, increasing, and strictly concave function of x_s and R_s . Information data rate for each source s may be constrained within a range $[x_s^{\min}, x_s^{\max}]$, and there may be a minimum

reliability requirement R_s^{min} . The reliability of source s is defined as $R_s = 1 - p_s^U$ where p_s^U is an end-to-end error probability for the flow from source s . Each link l has its maximum transmission capacity C_l^{max} . After link l receives the data of source s from the upstream link, it first decodes it to extract the information data and encodes it again with its own code rate, $r_{l,s}$, where code rate is defined as the ratio of the information data rate x_s (bps) at the input of the encoder to the transmission data rate $t_{l,s}$ (bps) at the output of the encoder [7]. This allows the link to adjust both transmission rate and error probability, since the transmission rate $t_{l,s}$ of source s at link l can be defined as

$$t_{l,s} = \frac{x_s}{r_{l,s}}$$

and the error probability of source s at link l can be defined as a function of $r_{l,s}$ by

$$p_{l,s}^L = E_l(r_{l,s}).$$

This function $E_l(r_{l,s})$ rarely has a closed-form analytic expression, and will be approximated through known bounds. The end-to-end error probability for each source s is $p_s^U = 1 - \prod_{l \in L(s)} (1 - p_{l,s}^L) = 1 - \prod_{l \in L(s)} (1 - E_l(r_{l,s}))$. Assuming small decoding error probability (i.e., $p_{l,s}^L \ll 1$), we can approximate the end-to-end error probability of source s as

$$p_s^U \approx \sum_{l \in L(s)} p_{l,s}^L = \sum_{l \in L(s)} E_l(r_{l,s}).$$

Hence, the reliability of source s can be written as

$$R_s \approx 1 - \sum_{l \in L(s)} E_l(r_{l,s}).$$

Since each link l has its transmission capacity C_l^{max} , the sum of transmission rates of sources that are traversing each link cannot exceed its transmission capacity, i.e.,

$$\sum_{s \in S(l)} t_{l,s} = \sum_{s \in S(l)} \frac{x_s}{r_{l,s}} \leq C_l^{max}, \quad \forall l.$$

III. INTEGRATED DYNAMIC RELIABILITY POLICY

We first investigate a more restrictive policy where a link provides the *same* code rate to each of the sources whose flows traverse it, i.e.,

$$r_{l,s} = r_l, \quad \forall s \in S(l), \quad \forall l,$$

and the NUM problem is formulated as

$$\begin{aligned} & \text{maximize}_{\mathbf{x}, \mathbf{R}, \mathbf{r}} \quad \sum_s U_s(x_s, R_s) \\ & \text{subject to} \quad R_s \leq 1 - \sum_{l \in L(s)} E_l(r_l), \quad \forall s \\ & \quad \sum_{s \in S(l)} \frac{x_s}{r_l} \leq C_l^{max}, \quad \forall l \\ & \quad x_s^{min} \leq x_s \leq x_s^{max}, \quad \forall s \\ & \quad R_s^{min} \leq R_s \leq 1, \quad \forall s \\ & \quad 0 \leq r_l \leq 1, \quad \forall l. \end{aligned} \quad (2)$$

In order to derive a distributed algorithm to solve the above problem and to prove convergence to global optimum, the critical properties of separability and convexity of problem (2) need to be carefully examined. Because of the physical

layer coding and rate-reliability tradeoff we introduced into the problem formulation, these two properties no longer trivially hold as in the basic NUM (1).

Integrated policy naturally leads to a decomposition of problem (2), since the second constraint can be written as

$$\sum_{s \in S(l)} x_s \leq C_l^{max} r_l, \quad \forall l. \quad (3)$$

The more complicated issue is convexity of function $E_l(r_l)$. If random coding based on M -ary binary coded signals is used, an upper bound on the error probability is [8]:

$$p_l < \frac{1}{2} 2^{-N(R_0 - r_l)},$$

where N is the block length and R_0 is the cutoff rate. Hence, if we take

$$E_l(r_l) = \frac{1}{2} 2^{-N(R_0 - r_l)},$$

it is a convex function for given N and R_0 . A more general approach is to use the random code ensemble error exponent [7] that upper bounds the decoding error probability:

$$p_l \leq \exp(-N E_0(r_l)),$$

where N is the codeword block length and $E_0(r_l)$ is the error exponent function. In general, $E_l(r_l) = \exp(-N E_0(r_l))$ may not be convex, even though it is known [7] that $E_0(r_l)$ is a convex function. The following lemma provides a sufficient condition for convexity of $E_l(r_l)$.

Lemma 1. If the absolute value of the first derivatives of $E_0(r_l)$ is bounded away from 0 and the absolute value of the second derivative of $E_0(r_l)$ is upper bounded, then for a large enough codeword block length N , $E_l(r_l)$ is convex.

Proof: Assume that there exist positive constants ϵ_1 and ϵ_2 such that $\| \frac{dE_0(r_l)}{dr_l} \| \geq \epsilon_1$ and $\| \frac{d^2 E_0(r_l)}{dr_l^2} \| \leq \epsilon_2$.

$$\begin{aligned} \frac{d^2 E_l(r_l)}{dr_l^2} &= N \exp(-N E_0(r_l)) (N \left(\frac{dE_0(r_l)}{dr_l} \right)^2 - \frac{d^2 E_0(r_l)}{dr_l^2}) \\ &\geq N \exp(-N E_0(r_l)) (N \epsilon_1^2 - \epsilon_2). \end{aligned}$$

Hence, $\frac{d^2 E_l(r_l)}{dr_l^2} > 0$ for $N > \frac{\epsilon_2}{\epsilon_1^2}$. ■

Throughout this paper, we assume that the conditions in the above lemma are true and the channel code is strong enough, i.e., N is large enough. In such cases, problem (2) is a convex and separable optimization problem, which can be solved by the following distributed algorithm where each source and each link solve their own problems only with local information and limited message passing. This distributed algorithm is derived by decomposing the dual problem of (2) (not shown explicitly in this summary), and we can interpret dual variables λ_l and μ_s as the price per unit rate to use link l and the price per unit reliability that the source s must pay to the network, respectively.

Algorithm 1.

In each iteration t , by solving the following problem (4)¹ over (x_s, R_s) , each source s determines its information data rate and desired reliability (i.e., $x_s(t)$ and $R_s(t)$) that maximize its net utility based on the prices $(\lambda^s(t), \mu_s(t))$ in the current iteration. Furthermore, by price update equation (5), the source offers price $\mu_s(t+1)$ per unit reliability for the next iteration.

Source problem and reliability price update at source s :

$$\begin{aligned} & \text{maximize}_{x_s, R_s} \quad U_s(x_s, R_s) - \lambda^s(t)x_s - \mu_s(t)R_s \\ & \text{subject to} \quad x_s^{\min} \leq x_s \leq x_s^{\max} \\ & \quad \quad \quad R_s^{\min} \leq R_s \leq 1, \end{aligned} \quad (4)$$

where $\lambda^s(t) = \sum_{l \in L(s)} \lambda_l(t)$.

$$\mu_s(t+1) = [\mu_s(t) - \beta(t)(R^s(t) - R_s(t))]^+, \quad \forall s, \quad (5)$$

where $R^s(t) = 1 - \sum_{l \in L(s)} E_l(r_l(t))$ and $\beta(t)$ is step size, which can be taken as β_0/t for some $\beta_0 > 0$.

Concurrently in each iteration t , by solving problem (6) over r_l , each link l determines its code rate (i.e., $r_l(t)$) that maximizes the ‘net revenue’ of the network based on the prices in the current iteration. In addition, by price update equation (7), the link adjusts its congestion price $\lambda_l(t+1)$ per unit rate for the next iteration.

Link problem and congestion price update at link l :

$$\begin{aligned} & \text{maximize}_{r_l} \quad \lambda_l(t)r_l C_l^{\max} - \mu^l(t)E_l(r_l) \\ & \text{subject to} \quad 0 \leq r_l \leq 1, \end{aligned} \quad (6)$$

where $\mu^l(t) = \sum_{s \in S(l)} \mu_s(t)$.

$$\lambda_l(t+1) = [\lambda_l(t) - \beta(t)(r_l(t)C_l^{\max} - x^l(t))]^+, \quad \forall l, \quad (7)$$

where $x^l(t) = \sum_{s \in S(l)} x_s(t)$.

In the above Algorithm 1, source s needs to know $\lambda^s(t)$, the sum of $\lambda_l(t)$ ’s of links that are along its path $L(s)$. This can be obtained by the notification from the links e.g., through acknowledgment packets. To carry out price update (5), the source needs to know the sum of error probabilities of the links that are along its path (i.e., its own reliability that is provided by the network, $R^s(t)$). This can be obtained by the notification from the links that determines the code rate for the source (by solving problem (6)) or obtained by the notification from the destination that measures the end-to-end reliability. To solve the link problem (6), each link l needs to know $\mu^l(t)$, the sum of $\mu_s(t)$ ’s from sources $s \in S(l)$ using this link l . This can be obtained by the notification from these sources. To carry out update (7), the link needs to know the aggregate information data rate of the sources that are using it (i.e., $x^l(t)$). This can be obtained by measuring it by the link itself.

With dual decomposition and Lemma 1, the following result can be proved using standard techniques in distributed gradient algorithm’s convergence proof:

¹Optimization problems (4) and (6) (also problems (11) and (13) in Algorithm 2) are convex optimization in only one or two variables with simple range constraints. Hence, they can be easily solved by using standard algorithms such as a gradient projection algorithm.

Theorem 1. By Algorithm 1, dual variables $\lambda(t)$ and $\mu(t)$ converge to the optimal dual solutions λ^* and μ^* and the corresponding primal variables $\mathbf{x}^*$, $\mathbf{R}^*$, and $\mathbf{r}^*$ are the globally optimal primal solutions of (2).

IV. DIFFERENTIATED DYNAMIC RELIABILITY POLICY

In this policy, a link may provide a *different* code rate to each of the sources traversing it. An example of practical code constructions that enable such a flexibility is the coding technique with embedded diversity recently proposed in [9], which allows data streams with different rate-reliability tradeoffs be embedded within each other.

The problem formulation in (2) needs to be generalized to the following:

$$\begin{aligned} & \text{maximize}_{\mathbf{x}, \mathbf{R}, \mathbf{r}} \quad \sum_s U_s(x_s, R_s) \\ & \text{subject to} \quad R_s \leq 1 - \sum_{l \in L(s)} E_l(r_{l,s}), \quad \forall s \\ & \quad \quad \quad \sum_{s \in S(l)} \frac{x_s}{r_{l,s}} \leq C_l^{\max}, \quad \forall l \\ & \quad \quad \quad x_s^{\min} \leq x_s \leq x_s^{\max}, \quad \forall s \\ & \quad \quad \quad R_s^{\min} \leq R_s \leq 1, \quad \forall s \\ & \quad \quad \quad 0 \leq r_{l,s} \leq 1, \quad \forall l, s \in S(l). \end{aligned} \quad (8)$$

The objective function and constraints of problem (8) are the same as those of problem (2) except that we have $r_{l,s}$ here instead of r_l . Due to this critical difference, problem (8) in general is neither a convex problem nor a separable one (since we may not modify the second constraint in this problem as in (3)). To resolve this issue, we transform problem (8) by first introducing the auxiliary variables $c_{l,s}$, which can be interpreted as the allocated transmission capacity to source s at link l . Then, the above problem can be reformulated as

$$\begin{aligned} & \text{maximize}_{\mathbf{x}, \mathbf{R}, \mathbf{r}} \quad \sum_s U_s(x_s, R_s) \\ & \text{subject to} \quad R_s \leq 1 - \sum_{l \in L(s)} E_l(r_{l,s}), \quad \forall s \\ & \quad \quad \quad \frac{x_s}{r_{l,s}} \leq c_{l,s}, \quad \forall l, s \in S(l) \\ & \quad \quad \quad \sum_{s \in S(l)} c_{l,s} \leq C_l^{\max}, \quad \forall l \\ & \quad \quad \quad x_s^{\min} \leq x_s \leq x_s^{\max}, \quad \forall s \\ & \quad \quad \quad R_s^{\min} \leq R_s \leq 1, \quad \forall s \\ & \quad \quad \quad 0 \leq r_{l,s} \leq 1, \quad \forall l, s \in S(l) \\ & \quad \quad \quad 0 \leq c_{l,s} \leq C_l^{\max}, \quad \forall l, s \in S(l). \end{aligned} \quad (9)$$

The second constraint in problem (8) is now decomposed into two constraints in problem (9): the second and third constraints. Here, the second constraint implies that the transmission data rate of each source at each link must be smaller than or equal to its allocated transmission capacity at the link, and the third constraint implies that the aggregate allocated transmission capacity to the sources at each link must be smaller than or equal to its maximum transmission capacity. In this formulation, each link explicitly allocates a transmission capacity to each of its sources. We can easily show that problem (9) is equivalent to problem (8), since at optimality, the second constraint in problem (9) is satisfied with the equality.

The next step of problem transformation is to take a log change of variable at the second constraint in problem (9)

and set $x'_s = \log x_s$ (i.e., $x_s = e^{x'_s}$). This reformulation turns problem (8) into the following equivalent problem:

$$\begin{aligned} & \text{maximize}_{\mathbf{x}', \mathbf{R}, \mathbf{r}, \mathbf{c}} \sum_s U'_s(x'_s, R_s) \\ & \text{subject to} \\ & R_s \leq 1 - \sum_{l \in L(s)} E_l(r_{l,s}), \quad \forall s \\ & x'_s - \log r_{l,s} \leq \log c_{l,s}, \quad \forall l, s \in S(l) \\ & \sum_{s \in S(l)} c_{l,s} \leq C_l^{\max}, \quad \forall l \\ & x_s^{\min} \leq x'_s \leq x_s^{\max}, \quad \forall s \\ & R_s^{\min} \leq R_s \leq 1, \quad \forall s \\ & 0 \leq r_{l,s} \leq 1, \quad \forall l, s \in S(l) \\ & 0 \leq c_{l,s} \leq C_l^{\max}, \quad \forall l, i \in S(l), \end{aligned} \quad (10)$$

where $U'_s(x'_s, R_s) = U_s(e^{x'_s}, R_s)$ and $x_s^{\min} = \log x_s^{\min}$ and $x_s^{\max} = \log x_s^{\max}$.

Note that problem (10) is separable but still may not be a convex optimization problem since the objective $U'_s(x'_s, R_s)$ may not be a concave function, even though $U_s(x_s, R_s)$ is a concave function. The following lemma provides a sufficient condition for its concavity. For notational simplicity, assume that $U_s(x_s, R_s)$ is additive in each variable (the general case is an easy extension), $U_s(x_s, R_s) = U_s^x(x_s) + U_s^R(R_s)$ (i.e., $U'_s(x'_s, R_s) = U_s^x(x'_s) + U_s^R(R_s)$), and $U_s^R(R_s)$ be a strictly concave function of R_s . Define

$$g_s(x_s) = \frac{d^2 U_s^x(x_s)}{dx_s^2} x_s + \frac{dU_s^x(x_s)}{dx_s}.$$

Lemma 2. If $g_s(x_s) \leq 0$, $U_s^x(x'_s)$ is a concave function of x'_s and $U'_s(x'_s, R_s)$ is a concave function of x'_s and R_s .

Proof: Since $x_s = e^{x'_s}$,

$$\begin{aligned} \frac{d^2 U'_s(x'_s)}{dx_s'^2} &= \frac{d^2 U_s^x(x_s)}{dx_s^2} \left(\frac{dx_s}{dx'_s} \right)^2 + \frac{dU_s^x(x_s)}{dx_s} \frac{d^2 x_s}{dx_s'^2} \\ &= e^{x'_s} \left(\frac{d^2 U_s^x(x_s)}{dx_s^2} e^{x'_s} + \frac{dU_s^x(x_s)}{dx_s} \right) \\ &= e^{x'_s} g_s(x_s). \end{aligned}$$

Hence, if $g_s(x_s) \leq 0$, $U_s^x(x'_s)$ is a concave function of x'_s ■

The condition of $g_s(x_s) \leq 0$ is equivalent to:

$$\frac{d^2 U_s^x(x_s)}{dx_s^2} \leq -\frac{dU_s^x(x_s)}{x_s dx_s}.$$

Since utility functions are increasing, $\frac{dU_s^x(x_s)}{dx_s}$ is a positive number. The above inequality states that the utility function needs to be not just concave (i.e., $\frac{d^2 U_s^x(x_s)}{dx_s^2} \leq 0$), but with a curvature that is bounded away from 0 by as much as $\frac{dU_s^x(x_s)}{x_s dx_s}$, i.e., the user utility function must be ‘elastic’ enough.

For example, consider the often-used utility functions [5]:

$$U_s^\alpha(x_s) = \begin{cases} \log x_s, & \text{if } \alpha = 1 \\ (1 - \alpha)^{-1} x_s^{1-\alpha}, & \text{otherwise} \end{cases}.$$

For this family of utility functions parameterized by α , Lemma 2 shows that problem (10) becomes a convex optimization problem if $\alpha \geq 1$.

After the above procedures of problem transformations, we are ready to provide a distributed algorithm based on dual decomposition to solve problem (10), and to prove the

performance guarantee on global optimality provided that the conditions in Lemmas 1 and 2 hold.

Algorithm 2.

Equations (4)-(7) are now replaced by (11)-(14). In contrast to Algorithm 1 that does not keep per-flow information on the links, in the more complex Algorithm 2, each link differentiates each of the flows through it by providing a different code rate $r_{l,s}$, a different congestion price $\lambda_{l,s}$, and an explicit capacity allocation $c_{l,s}$. In addition, the congestion price $\lambda_{l,s}$ is determined based on the allocated capacity $c_{l,s}$ and the transmission rate $x_s/r_{l,s}$ of each individual source that uses link l in Algorithm 2, while the congestion price λ_l is determined based on the aggregate transmission rate of sources that use link l and the transmission capacity of the link in Algorithm 1.

Source problem and reliability price update at source s :

$$\begin{aligned} & \text{maximize}_{x'_s, R_s} U_s(x'_s, R_s) - \lambda^s(t) x'_s - \mu_i(t) R_s \\ & \text{subject to} \quad x_s^{\min} \leq x'_s \leq x_s^{\max} \\ & \quad R_s^{\min} \leq R_s \leq 1, \end{aligned} \quad (11)$$

where $\lambda^s(t) = \sum_{l \in L(s)} \lambda_{l,s}(t)$.

$$\mu_s(t+1) = [\mu_s(t) - \beta(t)(R^s(t) - R_s(t))]^+, \quad \forall s, \quad (12)$$

where $R^s(\lambda(t), \mu(t)) = 1 - \sum_{l \in L(s)} E_l(r_{l,s}(\lambda(t), \mu(t)))$.

Link problem and congestion price update at link l :

$$\begin{aligned} & \text{maximize}_{r_{l,s}, c_{l,s}, s \in S(l)} \sum_{s \in S(l)} \{ \lambda_{l,s}(t) (\log c_{l,s} + \log r_{l,s}) \\ & \quad - \mu_s(t) E_l(r_{l,s}) \} \\ & \text{subject to} \quad \sum_{s \in S(l)} c_{l,s} \leq C_l^{\max} \\ & \quad 0 \leq c_{l,s} \leq C_l^{\max}, \quad s \in S(l) \\ & \quad 0 \leq r_{l,s} \leq 1, \quad s \in S(l). \end{aligned} \quad (13)$$

$$\begin{aligned} \lambda_{l,s}(t+1) &= [\lambda_{l,s}(t) - \beta(t) (\log c_{l,s}(t) + \log r_{l,s}(t) - x'_s(t))]^+ \\ & \quad \forall l, s \in S(l). \end{aligned} \quad (14)$$

Theorem 2. By Algorithm 2, dual variables $\lambda(t)$ and $\mu(t)$ converge to the optimal dual solutions λ^* and μ^* and the corresponding primal variables $\mathbf{x}^*$, $\mathbf{R}^*$, $\mathbf{c}^*$, and $\mathbf{r}^*$ are the globally optimal primal solutions of problem (10).

Extensions of Algorithms 1 and 2 to asynchronous version with constant step size can be carried out similar to those in [6].

V. NUMERICAL EXAMPLES

Fig. 1. Network topology and flow routes for rate-reliability tradeoff example.

We present numerical examples for a simple network shown in Figure 1. Utility function $U_s(x_s, R_s)$ for user s has the

Fig. 2. Globally optimal rate-reliability tradeoff of 3 of the end users, using the integrated dynamic reliability policy (Algorithm 1).

following standard form of concave utility:

$$U_s(x_s, R_s) = a_s \frac{x_s^{1-\alpha} - x_s^{\min(1-\alpha)}}{x_s^{\max(1-\alpha)} - x_s^{\min(1-\alpha)}} + (1 - a_s) \frac{R_s^{(1-\alpha)} - R_s^{\min(1-\alpha)}}{R_s^{\max(1-\alpha)} - R_s^{\min(1-\alpha)}}.$$

where a_s is a constant ($0 \leq a_s \leq 1$) that determines the relative weight between rate and reliability. The decoding error probability on each link l is assumed to be the following form: $p_l^L = \frac{1}{2} \exp(-N(1 - r_l))$ where N is the channel code block length and r_l the code rate for link l . We set $\alpha = 1.1$, $x_i^{\min} = 0.1$ (Mbps), $x_i^{\max} = 2$ (Mbps), $C_l^{\max} = 2$ (Mbps), $R_i^{\max} = 1$, and $R_i^{\min} = 0.9$.

We trace the globally optimal tradeoff curve between rate and reliability, and also compare the total network utility achieved by the following three policies:

- Static reliability
- Integrated dynamic reliability
- Differentiated dynamic reliability.

In the static scheme, each link provides a fixed error probability 0.025 and rate is allocated to each user by solving the basic NUM problem (1).

We first investigate the case where all the users have the same $a_s = a$, and vary the value of a from 0 to 1 in step size of 0.1. The resulting tradeoff curve obtained by Algorithm 1, which is globally optimal, is shown in Figure 2. As expected, a larger a (i.e., utility from rate given a heavier weight) leads to a higher rate at the expense of lower reliability. The more congested links a user's flow passes through, the steeper the tradeoff curve becomes. For each user, the area to the left and below of the tradeoff curve is the *achievable region*, and the area to the right and above of the tradeoff curve is the *infeasible region*. It is impossible to operate in the infeasible region and inferior to operate in the interior of the achievable region. Operating on the boundary of the achievable region, i.e., the Pareto optimal tradeoff curve, is the best.

We then give different weights a_s to the eight users:

$$a_s = \begin{cases} 0.5 - v, & \text{if } s \text{ is an odd number} \\ 0.5 + v, & \text{if } s \text{ is an even number} \end{cases}$$

and vary v from 0 to 0.5 in step size of 0.05. Figure 3 shows the relative performance in terms of network utility

Fig. 3. Comparison of the achieved network utility attained by each policy.

achieved by the three policies as v changes. The performance of Algorithms 1 and 2 that take into account rate-reliability tradeoff is significantly better than the standard distributed algorithm for the basic NUM (1) that ignores the possibility of jointly optimizing rate and reliability.

VI. CONCLUDING REMARKS

Motivated by needs from the application layer and possibilities at the physical layer, this paper removes the rate-dependency assumption on utility functions in the current NUM formulation and allows the physical layer adaptive channel coding to tradeoff rate and reliability on each link and for all the sources. We present two distributed algorithms for two possible formulations of the problem, and provide the sufficient conditions on codeword length and utility curvature under which convergence to the globally optimal rate-reliability tradeoff can be proved. In addition to link-updated congestion prices for distributed rate control, we also introduce source-updated signal quality prices for distributed reliability control. The tradeoff between packet drop probability and traffic load may be investigated similar to that between decoding error probability and transmission rate examined in this paper.
